Hormones and growth factors act on stromal and epithelial cells to regulate the development, maturation, and differentiation of mammary-gland cells.\(^1,2\) Broadly summarized, estrogen mediates the development and elongation of ductal tissue, progesterone facilitates ductal branching and lobulo–alveolar development, and prolactin regulates the production of milk protein. At puberty, estradiol and progesterone levels increase to initiate breast development. A complex tree-like structure results, comprising 5 to 10 primary milk ducts that originate at the nipple, 20 to 40 segmental ducts, and 10 to 100 subsegmental ducts that end in glandular units called terminal-duct lobular units.\(^3\) In the adult breast, cyclic changes occur during the menstrual cycle that result in an increased rate of cell proliferation during the luteal phase.\(^4\) An increase in breast size by up to 15 percent may occur during this phase.\(^4\) At menopause, the total number of lobules diminishes.

### Changes in the Normal Breast

The morphologic features of the breast undergo substantial change between early adolescence and menopause.\(^5\) The spectrum of normal histologic features ranges from a predominance of ducts, lobules, and intralobular and interlobular stroma to features that exhibit mainly patterns of fibrous change and cyst formation, formerly called fibrocystic disease of the breast. The term “fibrocystic changes” is now preferred, since in up to 50 to 60 percent of women without breast disease, this histologic pattern may be evident.\(^6\) The term “fibrocystic changes” implies that women with lumpy breasts or breasts with nondiscrete nodules do not have breast disease. The fibrocystic changes detected clinically entail no increased risk of breast cancer.

In women between adolescence and the mid-20s, the lobules and stroma in the breast may respond to hormonal stimuli in an exaggerated fashion with the development of single and multiple palpable fibroadenomas.\(^7\) In autopsy series, 15 to 23 percent of women in this age group were found to have fibroadenomas, whereas specialized clinics have found 7 to 13 percent among female patients in this age group and epidemiologic studies have found 2.2 percent.\(^5,8,9\) In the third and fourth decades of life, the degree of diffuse palpable nodularity may increase. In histologic terms, this increase represents adenosis — that is, enhancement of the amount of normal lobular tissue. The stroma may also undergo hypertrophy, resulting in palpable areas of ill-defined fullness, frequently in the axillary tail. In women between the middle of the fourth decade of life and menopause, glandular tissue may undergo further hypertrophy in association with an increase in stromal tissue. A higher prevalence of cyst formation is associated with late menopause, the use of hormone-replacement therapy, and a thin body composition.\(^8,10\)

### Classification of Benign Breast Lesions

In a practical classification, breast lesions that do not increase the risk of breast cancer are distinguished from those that confer a small increase in risk (relative risk, 1.5 to 2.0)
or a moderate increase (relative risk, >2.0) (Table 1). The levels of risk have been established by means of long-term follow-up, and the specific lesions were defined by a consensus conference. An important basis of the classification is the degree of cellular proliferation.

### Causal Factors in Benign Breast Disorders

Clinical observations of women receiving estrogens and antiestrogen drugs suggest that hormonal events play a causative role in the development of benign lesions. Among postmenopausal women receiving estrogens with or without progestins for more than eight years, the prevalence of benign breast lesions increased by a factor of 1.70 (95 percent confidence interval, 1.06 to 2.72). The antiestrogen drug tamoxifen, when used in the prevention of breast cancer, is associated with a reduction of 28 percent in the prevalence of benign breast lesions (relative risk, 0.72; 95 percent confidence interval, 0.65 to 0.79), including those classified as adenosis, cysts, mammary-duct ectasia, and hyperplasia.

Underlying and acquired genetic changes are also associated with benign breast lesions (Fig. 1). Loss of heterozygosity, as a result of deletions of small segments of DNA, is commonly found in benign breast lesions. Lesions are frequently multifocal, with each lesion exhibiting loss of heterozygosity of different regions of DNA. Women with mutations in the BRCA1 or BRCA2 genes have a high frequency of multiple benign or malignant breast lesions on meticulous examination of specimens obtained from bilateral mastectomy. These findings support the current theory of an underlying predisposition to mutations in some patients as the cause of multiple breast lesions. This phenomenon (i.e., a predisposition to mutations) has been termed a field effect and, more recently, a mutator phenotype.

### Progression to Malignant Disease

By analogy to the linear model of the development of colon cancer, breast lesions are believed by many investigators to progress in a linear fashion from usual ductal hyperplasia (ductal hyperplasia with...
out atypia) or from unfolded lobules to atypical ductal hyperplasia and then to ductal carcinoma in situ and invasive cancer. Several biologic and molecular changes (Fig. 1) have been observed in association with this progression, but causal relationships have not been established.

**BREAST PAIN**

Cyclic breast pain usually occurs during the late luteal phase of the menstrual cycle, in association with the premenstrual syndrome or independently, and resolves at the onset of menses (Table 2). In a study of 1171 healthy premenopausal American women, 11 percent had moderate-to-severe cyclic breast pain and 58 percent had mild discomfort. Breast pain interfered with usual sexual activity among 48 percent of the patients, and among others it interfered with physical activities (37 percent), social activities (12 percent), and school activities (8 percent). Whether caffeine, iodine deficiency, alterations in levels of fatty acid in the breast, fat intake in the diet, or psychological factors have a causative role in cyclic breast pain has not been established.

Noncyclic breast pain is unrelated to the menstrual cycle. Detection of focal tenderness is helpful diagnostically and suggests a tender cyst, rupture through the wall of an ectatic duct, or a particularly tender area of breast nodularity. Acute enlargement of cysts and peri ductal mastitis may cause severe, localized pain with a sudden onset.

**NONBREAST PAIN**

Pain arising from the chest wall may be mistakenly attributed to the breast. Pain that is limited to a particular area and characterized as burning or knife-like in nature may arise from the chest wall. Several distinct types of pain can be distinguished, including localized or diffuse lateral chest-wall pain, radicular pain arising from the chest wall, or pain associated with muscular strain.

---

**Figure 1. Progression from a Benign to a Malignant Lesion.**

Progression to malignant breast disease is associated with the accumulation of an increasing number of genetic mutations. Numbers at the right are factors by which the items listed on the left are increased in women with ductal carcinoma in situ. The rate of proliferation increases by a factor of five when benign breast tissue is compared with ductal carcinoma in situ. The DNA content, as represented by aneuploidy (more or less DNA than would be expected for the presence of 46 chromosomes) gradually increases. Aneuploidy is commonly present in ductal carcinoma in situ. Several studies have shown that levels of estrogen receptor α (ERα) increase, and one recent study showed a reduction in levels of estrogen receptor β (ERβ). The oncogene for transforming growth factor α (TGF-α) increases concomitantly with the appearance of hyperplasia. There is an increase in c-erbB-2 (HER2/neu) and in mutations of the tumor-suppressor gene p53 only in ductal carcinoma in situ. For references for data in this figure, see the Supplementary Appendix, available with the full text of this article at www.nejm.org.
pain from cervical arthritis, and pain from Tietze’s syndrome (costochondritis).

NIPPLE DISCHARGE
Among female patients referred to physicians because of symptoms of breast disorder, 6.8 percent have nipple discharge. Although this symptom is particularly distressing to the patient, only 5 percent of these patients are found to have serious underlying disease. Nipple discharge is considered to be pathologic if it is spontaneous, arises from a single duct, is persistent, and contains gross or occult blood. Age is an important factor with respect to the risk of malignant disease. In one series, among women with nipple discharge as their only symptom who were found to have cancer, 3 percent were younger than 40 years of age, 10 percent were between 40 and 60 years, and 32 percent were older than 60 years.

FOCAL AND DIFFUSE BREAST LUMPS
Discrete lesions detected by palpation or on routine mammography are different entities in women who are less than 30 years of age, 31 to 50 years, or older than 50 years. On a statistical basis, 9 of 10 new nodules in premenopausal women are benign (Table 1). Diffuse symmetrical lumpiness is commonly found on physical examination and is associated with fibrocystic changes on histologic examination.

Several pathologic entities are associated with an enhanced risk of breast cancer (Table 1). A recent report suggests that there is a slight increase in the risk of breast cancer among women more than 50 years of age with benign lesions that are in the lower category of risk: cyst, adenosis, mammary-duct ectasia, fibrosis, metaplasia, fibroadenoma, mild-to-moderate or florid hyperplasia without atypia, and papilloma. This study combined two groups of women in the lower category of risk: those with proliferative disease without atypia and those with nonproliferative disease (Table 1). A large study reported elsewhere in this issue of the Journal found an increased risk of breast cancer only among women with proliferative disease. Among women with nonproliferative lesions, only those with a strong family history of breast cancer were at increased risk.

† Usual ductal hyperplasia, atypical ductal hyperplasia, and atypical lobular hyperplasia may be detected incidentally in female patients undergoing biopsy of masses with other causes, such as fibroadenomas and fibrocystic changes.
Breast density on mammographic screening is also a risk factor, with an increase in relative risk by a factor of five for the highest density.\(^{39-42}\) (Fig. 2). Dense breasts contain a higher proportion of stromal and glandular tissue as well as an increased number of lesions classified as usual ductal hyperplasia and atypical ductal hyperplasia.\(^{40}\) According to classic studies in twins, heritability accounts for approximately 60 percent of the variation in breast density.\(^{42}\)

The risk of breast cancer is also increased in association with high plasma levels of free estradiol and testosterone in postmenopausal women.\(^{43,44}\) weight gain of 20 kg (44 lb) or more after menopause, early menarche, late menopause, late childbearing, and a family history of breast cancer.\(^{45}\) However, it is not known whether the increased risk associated with breast density or specific histologic lesions adds to these other known risks or whether these factors are merely dependent variables.\(^{44,45}\) \(\text{BRCA1}\) carriers have a 65 percent probability (95 percent confidence interval, 44 to 78 percent) of developing breast cancer by 70 years of age, and \(\text{BRCA2}\) carriers have a 45 percent probability (95 percent confidence interval, 31 to 56 percent).\(^{46}\) Studies are under way to evaluate the use of nipple aspiration and ductal lavage as additional means of risk stratification.\(^{47}\) Currently, the Gail and Claus models are commonly used as practical means of estimating the risk of breast cancer, but these models use only a limited number of variables and are not powerful in predicting disease.\(^{48,49}\)

### Practical Management

A detailed history and physical examination are used to evaluate systematically the entire breast and the chest wall and should focus on areas related to the patient’s symptoms (Table 3). The sensitivity and specificity of the clinical breast examination are estimated to be 54 percent and 94 percent, respectively, and depend on the thoroughness and technique of the examiner.\(^{50}\) Diagnostic studies may then be ordered. The “triple test” of lumps includes palpation, imaging, and percutaneous biopsy (i.e., core needle biopsy or fine-needle aspiration). Mammography, often in conjunction with ultrasonographic examination,\(^{51-54}\) is required for evaluation of dis-
crete palpable lesions in women more than 35 years of age; ultrasonography provides an optional substitute among younger women. Round dense lesions detected on mammography often are cysts that require ultrasonographic examination to distinguish them from solid lesions.

For solid lesions, core needle biopsy directed with the use of radiographic or ultrasonographic techniques provides highly discriminative information with regard to the presence or absence of malignant disease. In core needle biopsy, a large cutting needle is used with a spring-loaded, automated biopsy instrument to obtain tissue specimens suitable for histologic analysis. Fine-needle aspiration yields cellular material suitable for cytologic evaluation, but the technique must be used by an experienced cytopathologist and the specimen obtained is insufficient for diagnosis in up to 36 percent of cases in which there are nonpalpable lesions.39

The roles of magnetic resonance imaging (MRI) and digital mammography in the evaluation of breast lesions are currently being investigated. Galactography (also called ductography) is useful in the detection of focal lesions within a single duct. Cytologic examination of nipple discharge is of limited value, with a sensitivity for detecting malignant disease of only 35 to 47 percent.34,56 In the treatment of all patients with benign breast disease, clinical judgment is required to provide the proper balance between the intense and frequent surveillance needed for some patients and the risk of overdiagnosis and treatment for others.

# Treatment

### Cyclic Breast Pain

The most important issue in the management of cyclic breast pain is to decide whether to treat. In the absence of a mass or discharge, mild symptoms warrant reassuring the patient regarding the absence of serious disease.57 Among 85 percent of women evaluated in large referral clinics,58 watchful waiting without treatment was considered acceptable after their anxiety about malignant disease was alleviated, whereas the remaining 15 percent requested treatment. Several clinics specializing in breast disorders administer tamoxifen and danazol for breast pain and have conducted randomized, placebo-controlled, clinical trials to demonstrate the efficacy of these strategies. Data on secondary end points from the International Breast Cancer Intervention Study, involving 7152 women who received tamoxifen for adjuvant therapy for breast cancer, provide additional evidence of the efficacy of this agent in relieving mastalgia.59 Several other therapies are probably beneficial, on the basis of physiologic principles. Precise fitting of a brassiere to provide support for pendulous breasts may provide pain relief.60 Lowering the dose of estrogens in the treatment of postmenopausal women or the addition of an androgen to estrogen-replacement therapy appears to be beneficial in reducing breast pain. The use of oral contraceptives has not been systematically studied, but preparations that contain low-dose estrogen (20 µg of ethinyl estradiol) and 19-nor progestins may produce relief.55,61,62

No standard regimen for moderate-to-severe breast pain has been widely accepted. Initial recom-
mendations may include the use of mild analgesic agents such as acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), or aspirin.\textsuperscript{52,53,56,63-67} Other approaches include tamoxifen, at a dose of 10 mg daily for three to six months,\textsuperscript{68,69} and among patients in whom there is no response to treatment, a change to danazol, at a dose of 200 mg daily (or only during the luteal phase of the menstrual cycle).\textsuperscript{70} Evening primrose oil has been used, at oral doses of 1 to 3 g daily, on the basis of two randomized studies,\textsuperscript{71,72} but recent trials question its efficacy.\textsuperscript{73,74} Gonadotropin-releasing hormone agonists have been used successfully for severe pain.\textsuperscript{75,76}

\textbf{NONCYCLIC PAIN}

When pain is truly arising from the breast, the approach outlined for cyclic pain is used. However, a musculoskeletal cause is present in 40 percent of women referred to specialized mastalgia clinics for pain thought to arise from the breast. In two thirds of women with diffuse chest-wall pain, the condition responds to oral or topical NSAIDs.\textsuperscript{77} Among the remaining patients, 85 percent gain temporary or permanent relief from the use of a combination of anesthetic and steroidal drugs injected into the tender site.\textsuperscript{77}

\textbf{FOCAL LESIONS}

Careful examination distinguishes between solitary, discrete, dominant, persistent masses and vague nodularity and thickening. The Society of Surgical Oncology practice guidelines\textsuperscript{78} recommend the following evaluation. In women 35 years of age or younger, all dominant, discrete, palpable lesions require referral to a surgeon. If vague nodularity, thickening, or asymmetric nodularity is present, the examination should be repeated at midcycle after one or two menstrual cycles. If the abnormality resolves, the patient should be reassured, and if it does not, the patient should be referred to a surgeon. Breast imaging may be appropriate. Women older than 35 years of age with a dominant mass should undergo diagnostic mammography (and frequently, ultrasonography)\textsuperscript{51,54,55} and should then be referred to a surgeon. When vague nodularity or thickening is present, mammographic screening is required, with physical examination repeated at midcycle one to two months afterward and referral to a surgeon if the abnormality persists.

Postmenopausal women are referred for surgical consultation after undergoing mammography. For gross cysts, the guidelines suggest fine-needle aspiration with imaging studies repeated within six months. Nonbloody fluid is discarded, but if the same cyst refills, surgical consultation is warranted. If bloody, the fluid should be sent for cytologic analysis and consultation with a surgeon should be requested.

Usual practice requires the triple test (palpation; mammography, often in conjunction with ultrasonography; and biopsy) for women more than 35 years of age with dominant masses. When the results of mammographic screening are negative but a dominant mass is present, biopsy is required to rule out breast cancer, since lobular carcinoma may not be visible on mammography. Among younger women, mammography may be omitted if the results of ultrasonographic testing and biopsy yield definitive information. Many experts omit biopsy in the evaluation of younger women with lesions characteristic of fibroadenoma on ultrasonography and elect to follow these patients carefully with serial ultrasonography at six-month intervals for a period of two years and once yearly thereafter. Since careful studies have shown that a lesion that appears to be benign on mammography and ultrasonography is benign more than 99 percent of the time, some experienced clinicians opt for follow-up without biopsy.\textsuperscript{51-54} However, other experienced surgeons disagree and believe that all fibroadenomas require diagnostic core needle biopsy or fine-needle aspiration, especially among carriers of a BRCA mutation, in whom medullary cancer may be found. Confirmation on biopsy of fibroadenoma eliminates the need for serial ultrasonography. For patients with a diagnosis of atypical ductal hyperplasia on fine-needle aspiration or core needle biopsy, excisional biopsy is required, because more complete resection often changes the diagnosis to ductal carcinoma in situ.

\textbf{NIPPLE DISCHARGE}

A practical algorithm (Fig. 3) divides discharge into two categories according to the presence or absence of galactorrhea (defined as milk production more than one year after weaning or in nulligravid or menopausal women). The presence of a discharge in association with a palpable mass and positive results on mammography or ultrasonography warrants evaluation of the mass. Galactorrhea is considered pathologic if spontaneous. A workup for galactorrhea includes measurement of prolactin and thyrotropin levels and appropriate endocrinologic evaluation and treatment if the levels are ele-
Figure 3. Algorithm for the Evaluation of Breast Discharge.

In the presence of the involvement of multiple ducts, if there is a spontaneous and persistent discharge of gross blood from a single duct, galactography should be considered.
Prevention of Breast Cancer

Patients with benign breast lesions that impart an increased risk of breast cancer can be offered tamoxifen as a preventive strategy. The risk of breast cancer is determined with the use of the Gail model (or among women with a family history that includes second-degree maternal or paternal relatives with breast cancer, the Claus model). Decisions are based on an evaluation of the benefits as compared with the risks of tamoxifen (http://smi-web.stanford.edu/people/pcheng/breastca). Risk factors not included in either the Gail or the Claus model include the degree of breast density, plasma levels of free estradiol, bone density, weight gain after menopause, and waist-to-hip ratio. Current recommendations suggest that women with a five-year risk of breast cancer of more than 1.67 percent and no contraindications to tamoxifen therapy should be informed about the option of taking tamoxifen for five years.
